AND A PAGE OF JAVASCRIPT
EXAMPLE CODE AND GUESSED
AT EVERYTHING IN BETWEEN.

Learning Objectives

- Understand what is an STL container adaptor and know how to use it (for stack and queue)
- Understand what is an associative container and know how to use its STL implementation map

Outline

- Container Adaptors
- ADT: Dictionary
- Associative Container: map

Adaptor

- An adaptor is a mechanism for making one thing act like another
 - A container adaptor takes an existing container type and makes it act like a different abstract data type
- Three sequential container adaptors
 - stack ✓
 - queue 🗸
 - priority_queue
- To use stack, #include <stack>
- To use queue, #include <queue>

Initializing an Adaptor

- A a;
 - The default adaptor. Create an empty object
 - E.g. stack<int> stk;
- A a(c);
 - Take a container and make a copy of that container as its underlying value
 - By default, both stack and queue are implemented using deque, so if you use a <u>sequential container</u> C to initialize, C must be a deque type

```
deque<int> deq(10, 1);
stack<int> stk(deq);
```

Initializing an Adaptor

• How do we use a vector to initialize a stack?

```
// Assume ivec is vector<int>
stack<int,vector<int>_> stk(ivec);
```

Note the **space**. Otherwise, treated as an extraction operator — an error!

• We can use vector, list, and deque to build stack

To build a queue, we can use:

Select all the correct answers.

- A. vector.
- **B.** list.
- C. deque.
- D. stack.

Operations of Stack Adaptor

- s.empty()
 - Returns true if the stack is empty; false otherwise
- s.size()
 - Returns a count of the number of elements of the stack
- s.pop()
 - Removes, but does not return, the top element from the stack
- s.push(item)
 - Places a new top element of the stack
- s.top()
 - Returns a reference to the top element of the stack

Note: although stack is implemented using another container, you cannot use other operations. For example, cannot call push_back().

Example

```
stack<int> stk;
for(int i=0; i<5; i++)
    stk.push(i);
while(!stk.empty()) {
    cout << stk.top() << endl;
    stk.pop();
}</pre>
```

What's the output?

Operations on Queue Adaptor

- q.empty()
 - Returns true if the queue is empty; false otherwise
- q.size()
 - Returns a count of the number of elements of the queue
- q.push(item)
 - Places a new element at the end of the queue
- q.pop()
 - Removes, but does not return, the front element from the queue
- q.front()
 - Returns a reference to the front element of the queue
- q.back()
 - Returns a reference to the back element of the queue

Outline

- Container Adaptors
- ADT: Dictionary
- Associative Container: map

Dictionary

- How do you use a dictionary?
 - Look up a "word" and find its meaning.
- We also have an ADT of dictionary.
 - It is a collection of pairs, each containing a key and an value (key, value)
 - Important: Different pairs have different keys.

tional industrial labor union that was organized in Clin 1905 and disintegrated after 1920. Abbr.: I.W.W., In.dus.tri.ous (in dus/trē əs), adj. 1. hard-working gent. 2. Obs. skillful. [< L industrius, OL indostru disputed origin] —in.dus/tri.ous.ly, adv. —in.du ous.ness, n. —Syn. 1. assiduous, sedulous, energeti busy. —Ant. 1. lazy, indolent.

in.dus.try (in/də strē), n., pl. -tries for 1, 2. 1. the gate of manufacturing or technically productive enter in a particular field, often name lafter its principal processing any general business field. In a de or manufacturing or technically productive enter in a particular field, often name lafter its principal processing any general business field. In a de or manufacturing or labor. 6. assiduous activity ar ny work or

Dictionary

- Key space is usually more regular/structured than value space, so easier to search.
- Dictionary is optimized to quickly add (key, value) pair and retrieve value by key.

Methods

- Value find (Key k): Return the value whose key is k. Return Null if none.
- void insert (Key k, Value v): Insert a pair
 (k, v) into the dictionary. If the pair with key as k already exists, update its value.
- Value remove (Key k): Remove the pair with key as k from the dictionary and return its value. Return Null if none.
- int size(): return number of pairs in the dictionary.

Example

- Collection of student records in the class
 - (key, value) = (student name, <u>linear list</u> of assignment and exam scores)
 - All keys are distinct
- Operations
 - Get the value whose key is John Adams.
 - Insert a record for the student whose name is Diana Ross.

Implementation

- Method #1: using an array
 - Just like our **IntSet**
 - The difference is that each array element is a (key, value) pair
 - If keys can be sorted, can use either sorted array or unsorted array on keys
- Method #2: using a linked list
 - Each node now stores both the key and value
 - The differences over **IntList** are:
 - When inserting, it needs to verify there is no duplicated key.
 If key already exists, update the value entry
 - It removes on key, not just the first and last element

Outline

- Container Adaptors
- ADT: Dictionary
- Associative Container: map

Introduction

- Elements in an associative container are stored and retrieved by a **key**, in contrast to elements in a sequential container, which are stored and accessed sequentially by their position within the container
- Two primary associative container types: map and set
 - Elements in a map are (key, value) pairs
 - set contains only a key and supports efficient queries to whether a given key is present
- Applications
 - map: dictionary
 - set: store a collection of distinct values efficiently. For example, the distinct English words in an article

Associative vs. Sequential Containers

- Associative containers share many, but not all, of the operations on sequential containers
 - They <u>do not</u> have the front(), push_front(), pop_front(), back(), push_back(), or pop_back() operations
- Common operations
 - C<T> c; // creates an empty container
 - C<T> c1 (c2); // copies elements from c2 into c1 // c2 must be the same type as c1
 - C<T> c(b, e); // b and e are iterators denoting a // sequence. Copy elements from the sequence into c
 - begin(), end(), size(), empty(), clear(), =

Associative vs. Sequential Containers

- The associative container types define additional operations
- The big difference: for associative containers, elements are accessed by key
 - We focus here on associative containers where the elements are ordered by key (not in the order of their insertions)
 - When we iterate across such an associative container, we are guaranteed that the elements are accessed in key order, irrespective of the order in which the elements were placed in the container.

Map

- map is also known as **associative array**
- It stores (key, value) pair
- To use it, #include <map>
- Constructors
 - map<k, v> m; // Create an empty map named m
 // with key and value types k and v.
 - E.g., map<string, int> word_count
 - map<k, v> m (m2); // Create m as a copy of m2;
 // m and m2 must have the same key and value types
 - map<k, v> m(b, e); //Create m as a copy of the //elements from the range denoted by iterators b and e

Constraints on the Key Type

- Since elements in map are ordered by keys, we require that key type has an extra operation: **strict weak ordering**
- Strict weak ordering:
 - Think as less than (<)
- Technically
 - Yield false when we compare a key with itself
 - Given two keys, they cannot both be "less than" each other
 - Satisfy transitive property: if k1<k2 and k2<k3, then k1<k3
 - If we have two keys, neither of which is "less than" the other, then they are treated as equal

Examples:

- < for int
- alphabetical order for string

Preliminaries: the pair Type

- A simple companion type, holding two data values
- It is a template. Need to supply two type names pair<string, string> spair; // hold two strings
- pair<T1, T2> p1;
 - Create a pair with two elements of types T1 and T2. The elements are value-initialized (use default constructor for class type; 0 for built-in type)
- pair<T1, T2> p1(v1, v2);
 - Create a pair with types T1 and T2. Initialize the first member from v1 and the second from v2.
 - pair<string, int> count("blue", 2);

Preliminaries: the pair Type

- We can access the two data members in the pair
 - p.first // return the reference to the first member
 - p.second // return the reference to the second member
 - They are **public**
- make_pair(v1,v2)
 - Create a new pair from the values v1 and v2. The type of the pair is inferred from the types of v1 and v2

```
pair<string, string> name = make_pair("John",
"Adams");
```

Map Iterator

• Dereferencing a map iterator yields a **pair** in which the first member holds a **const key** and the second member holds the **value**

- *it is a reference to a pair < const string, int > object
 - It refers to neither the key nor the value
- To access its key, use it->first cout << it->first;
- However, the first member is a **const key**, so we cannot change it

```
it->first = "new key"; // Error!
```

Map Iterator

To access its value, use it->second
 cout << it->second;

We can change value through iteratorit->second = 2;

Adding Elements to a map

- There are two ways:
 - Using the subscript operator
 - Using the insert member

Insert Using Subscripting

• If key k is not in the map m, you can insert (k, v) using m[k] = v;

Example

```
map <string, int> word_count; // empty map
// insert element with key "Anna";
// then assign 1 to its value
word_count["Anna"] = 1;
```

• You inserted a pair ("Anna", 1) into word count.

Insert Using Subscripting

```
map <string, int> word_count; // empty map
// insert element with key "Anna";
// then assign 1 to its value
word_count["Anna"] = 1;
```

- What really happens is
 - word_count is searched for the element whose **key** is **Anna**. The element is not found.
 - A new (key, value) pair is inserted. key = "Anna". Value is value-initialized to 0.
 - The newly inserted element is fetched and is given the value 1.

Subscripting a map

- Subscripting a map behaves quite differently from subscripting an array or vector
 - Using an index (key) that **does not exist** adds an element with that index to the map

// and add one to it

If the key exists, the value associated with the key is returned. We can read and write to the value cout << word_count["Anna"]; ++word count["Anna"]; // fetch the element

- Subscripting a vector = dereferencing a vector iterator
- Subscripting a map ≠ dereferencing a map iterator

Use Subscript Behavior in a Smart Way

- The first time we encounter a word, a new element indexed by word is created and inserted into map
 - Its value is initialized with zero
- Then, the value of that element is immediately incremented. So, the count is the (correct) value of one
- If word is already in the map, then its value is incremented.

insert()

- m.insert(e)
 - \bullet e is a (key, value) pair. If the key is not in m, insert the pair. If the key is in m, then m is unchanged

```
word_count.insert(make_pair("Anna", 1));
```

insert()

- m.insert(e)
 - Returns a pair of (map iterator, bool)
 - map iterator refers to the element with key
 - bool indicates whether the element was inserted or not.

```
// count #times each word occurs from input
map<string, int> word_count;
while (cin >> word) {
   pair<map<string, int>::iterator, bool> ret =
        word_count.insert(make_pair(word, 1));
   if (!ret.second) // word already in word_count
        ++ret.first->second; // increment count
}
```

Finding and Retrieving a map Element

- The subscript operator provides the simplest method of retrieving a value
- But, it has a side effect. What is it?
 - If that key is not already in the map, then subscript inserts an element with that key.
- How can we determine if a key is present without causing it to be inserted?
 - m.find(k)

find()

- m.find(k)
 - Returns an iterator to the element indexed by key k, if there is one
 - Otherwise, returns an off-the-end iterator (i.e., end()) if the key is not present

```
int occurs = 0;
map<string,int>::iterator it =
  word_count.find("abc");
if (it != word_count.end())
  occurs = it->second;
```

erase()

- m.erase(iter)
 - Removes element referred to by the iterator iter from m. iter must refer to an actual element in m; it must not be equal to m.end().
 - Returns void.
- m.erase(k)
 - Removes the element with key k from m if it exists
 - Otherwise, do nothing
 - Returns the number of elements removed. For map, this is either 0 or 1

```
if (word_count.erase(rm_word)) // rm_word is a key
  cout << "ok: " << rm_word << "removed\n";
else cout << rm_word << " not found!\n";</pre>
```

Iterate across a map

- map has begin () and end (), with which we can traverse the map
- Example: print all the elements in word_count

- The output prints the words in **alphabetical order**.
 - <u>Note</u>: When we use an iterator to traverse a map, the iterators yield elements in <u>ascending key order</u>.

Which of the following statements are true?

Select all the correct answers.

- A. A dictionary can be seen as a generalization of an array.
- **B.** A key has to be a string.
- C. A same key can be associated to several different values in a dictionary.
- **D.** A same value can be associated to several different keys in a dictionary.
